ABSTRACT

We report the first measurement of the X-ray spectrum of the z = 5.99 quasar SDSSp J130608.26+035626.3 from a 120 ks observation by the Chandra ACIS-S instrument. Between 0.5 and 7 keV, corresponding to 3.5–49 keV in the quasar rest frame, we find an energy index of 0.86 ± 0.2, consistent with the typical indices found for radio quiet quasars at lower redshifts, and inconsistent with the index required to match the diffuse X-ray background. We have a weak indication of a redshifted Fe-K line. In comparing the counting rate between an earlier, short observation and the longer observation reported here, we find evidence for source variability at the 99.9% confidence level. We note that other nearby X-ray sources would bias the measured \( \alpha_{\text{ox}} = 1.70 \) by \(-0.09\) if the X-ray flux were determined from within a 60″ extraction circle. Our results for the energy index and the \( \alpha_{\text{ox}} \) are consistent with no strong evolution in the active galactic nucleus emission mechanism with redshift out to \( z \approx 6 \), and therefore with the picture that massive black holes have already formed less than 1 Gyr after the big bang.

Subject headings: quasars: general—quasars: individual (SDSSp J130608.26+035626.3)—X-rays: galaxies

1. INTRODUCTION

The Sloan Digital Sky Survey has revealed the most distant quasars known (Fan et al. 2001, 2004). Chandra observations on 2002 January 29 easily detected three quasars at redshifts 5.82, 6.28, and 5.99 in brief, \( \approx 5–8 \) ks, ACIS-S observations (Schwartz 2002; Brandt et al. 2002; Mathur et al. 2002; Bechtold et al. 2003). The latter, SDSSp J130608.26+035626.3 (hereafter, J1306), was followed up with a 120 ks Chandra observation, based on the claim by Schwartz (2002) of an associated jet. Ivanov (2002) subsequently identified the X-rays attributed to a jet with a faint galaxy, and the present observation clearly confirms the galaxy identification.

From the optical observations, J1306 is a broad line quasar, whose spectrum contains Ly\( \alpha \)+NV emission, and various intervening absorption systems (Fan et al. 2001; Becker et al. 2001). This is a general characteristic of the 12 quasars now known at \( z \approx 6 \) (Fan et al. 2004). From the optical absolute magnitude \( M_{1450} = -26.93 \) (Fan et al. 2001), the central black hole mass must be at least \( 10^9 M_\odot \), unless it is emitting at much greater than the Eddington luminosity.

We report here a study of the X-ray variability and spectrum of J1306. The X-ray spectrum of distant quasars is of interest to search for possible evolution of the active galactic nucleus (AGN) emission mechanism, which might give clues to the history of the formation and the fueling of the central massive black hole. With AGNs widely inferred to make up the bulk of the diffuse X-ray background, it remains to define the model of quasar evolution and of the relative numbers of absorbed and unabsorbed emitters that will reproduce the shape of the 2–10 keV diffuse X-ray background to the precision measured by Marshall et al. (1980). It remains possible that a high fidelity spectral fit must also consider a contribution from quasars with concave curvature in their spectrum.
from 5 to 40 keV, as suggested by Schwartz & Tucker (1988).

Previous measurements of radio-quiet quasars in the redshift range 2.64–4.35 gave photon spectral indices $\Gamma \approx 2.0$ (Ferrero & Brinkmann 2003; Brocksopp et al. 2004; Grupe et al. 2004), with the exception of an index 1.4 reported by Brocksopp et al. (2004) for RX J122135.6+280613 at $z=3.305$. Yuan et al. (1998) report a mean index $\Gamma \approx 2.23 \pm 0.15$ for 56 ROSAT quasars with $z > 2.0$. The result reported here provides an example at $z=5.99$ with $\Gamma=1.86$.

2. OBSERVATIONS OF J1306

J1306 was observed with the back-illuminated S3 CCD of the Advanced CCD Imaging Spectrometer (ACIS) at the nominal aim point for approximately 118 ks live time starting on 2003 November 29. The Chandra data were reduced in the standard manner using CIAO version 3.0.2 and the latest calibration database (CALDB) release (ver. 2.26; released 2004 February 2) which incorporates an improved ACIS contamination calibration file and corrects a one-channel offset in the ACIS S3 response matrix. The contamination correction is required since the degradation of the effective ACIS throughput is strongly energy dependent. Only events for ASCA grades 0, 2-4, and 6 were retained for analysis. We restrict the energy range to 0.5–7.0 keV, as the background rises steeply below and above those limits. However, no photons greater than 5.1 keV were detected. We applied “corr_gain.1.0”$^2$ to the event list to correct the measured X-ray energy for the secular gain drift which is primarily caused by gradual deterioration of the charge transfer inefficiency of the ACIS CCDs. We checked that no background flares occurred during the observation. We also inspected the individual photon arrival times from the quasar and there is no evidence for transient phenomena affecting the data.

Figure 1 shows the field within 1′ of the quasar. CXOU 130609.31+035643.5, a point source approximately 24″ to the northeast from J1306, is the faint I-band galaxy found by Ivanov (2002) and now confirmed as the correct identification rather than the suggestion of a jet (Schwartz 2002). Figure 2 shows the light curve for J1306 during the earlier short observation (ObsID 3358) and the present long observation (ObsID 3966). We detected 18 photons between 0.5 and 7.0 keV in 8.16 ks during the 2002 January observation. However, based on the counting rate of the present observation, only 8 photons are expected. The probability of observing 18 photons when 8 are expected is only 0.1%. Therefore, this suggests that we see intrinsic variability in the source between these two epochs. Weak evidence of variability within the current observation would require better statistics to confirm. Note that the elapsed time of 22 months between the two observations corresponds to a time scale of 3.15 months in the source frame.

3. THE X-RAY SPECTRUM

The X-ray spectrum was extracted using a circular region with a 3″ radius centered on the brightest pixel.$^3$ The background was taken from

\[ \text{CXOU J130609.31+035643.5} \]

\[ \text{SDSS J130608+035626} \]

Fig. 1.— Circle indicates a 1′ radius around J1306. The pointlike source CXOU 130609.31+035643.5 is the faint I-band galaxy found by Ivanov (2002). Several other weak sources appear in the region, and they would bias the measured $\alpha_{ox}$ in an observation with much poorer angular resolution.

$^3$These data and appropriate background were made publicly available immediately following the observations at http://asc.harvard.edu/acis/dschwartz.html
Fig. 2.— Light curve of J1306 during the short observation (ObsID 3358) and the present observation (ObsID 3966). The gap between the two observations is 22 months. We plot the total number of photons between 0.5 and 7 keV, within a 3′′ radius of the quasar, sorted into 3 ks bins.

Fig. 3.— X-ray spectrum of J1306 observed between 0.5 and 7.0 keV. The solid histogram gives the best fit power law model, with absorption fixed at the Galactic value.

Fig. 4.— Same as Figure 3 but with a redshifted 6.4 keV Fe-K emission line. The line energy is fixed at 0.916 keV, and the intrinsic width of the Gaussian is fixed to 0.

The photons were grouped, using the CIAO tool dmgroup, into 100 eV bins. Because of the small number of photons in most bins, the Cash statistic (Cash 1979) was used as the figure of merit in spectral fits performed within XSPEC (Arnaud 1996). We fit the spectrum to a power law, with galactic absorption fixed at its measured value of $2 \times 10^{20}$ H-atoms cm$^{-2}$ (Stark et al. 1992). This is shown in Figure 3. The fit is obviously adequate, and gives an energy spectral index $\alpha = 0.96 \pm 0.18$. The Galactic absorption-corrected flux in the observed 0.5–7.0 keV band is $6.1 \times 10^{-15}$ ergs cm$^{-2}$ s$^{-1}$. For $H_0 = 71$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.27$, and $\Omega_A = 0.73$, we derive an X-ray luminosity of $2.2 \times 10^{45}$ ergs s$^{-1}$ emitted in the source frame 2–10.0 keV band.

The residuals apparent below 1 keV hint at the possibility of redshifted Fe-K emission. If we add a narrow Gaussian line to the fit model, with the line energy fixed at 0.916 keV for redshifted neutral iron and the line $\sigma$ fixed at the intrinsic S3 resolution at the source position on the CCD, we derive the fit shown in Figure 4. The power-law energy index is slightly flatter, $\alpha = 0.86 \pm 0.20$, and the power-law normalization decreases by about 10%. The Cash statistic decreases by about 3.3. Although this would formally be 93% significance (Cash 1979), Protassov et al. (2002) point out that the likelihood ratio test is not valid for such an additive component to a spectral model. The chance that Poisson statistics leads to the residuals be-
tween 800 and 1000 eV in Figure 3 is 12.7%, so clearly further confirmation is needed for this feature. If real, the equivalent width of the the Fe-K emission line would be approximately 114 eV. Figure 5 shows the joint contours for the X-ray slope $\alpha_X$ and the amplitude of the Fe-K line.

We compute $\alpha_{ox}$ according to the original definition of Tananbaum et al. (1979),

$$\alpha_{ox} = -\log(S_x/S_o) / \log(\nu_x/\nu_o),$$

where $S_x$ is the X-ray flux density at 2 keV, $\nu_x = 4.8 \times 10^{17}$ Hz, and $S_o$ is the optical flux density at 2500 Å, $\nu_o = 1.2 \times 10^{15}$ Hz. We calculated the optical monochromatic luminosity at rest-frame 2500 Å using the observed optical flux (Fan et al. 2001) and assuming a power law optical continuum slope with $\alpha_o = 0.5$. This yields a value for $\alpha_{ox}$ of 1.70. This result is consistent with the values determined in the earlier observations, with small differences due to the fact that the previous conversion of counts to flux density merely assumed an energy index of 0.7 or 1.0 by Schwartz (2002) and Brandt et al. (2002), respectively, and that the source flux in the present observation is only half that in 2002 January. We note that an X-ray flux extraction circle of $60''$ radius would lead to a decrease in $\alpha_{ox}$ to 1.61, because of the inclusion of flux from other nearby X-ray sources, principally CXOU 130609.31+035643.5, as can be seen in Figure 1.

4. DISCUSSION

In this Letter, we present the first Chandra X-ray spectrum of a $z \sim 6$ quasar. The values for the energy index and the $\alpha_{ox}$ derived from this Chandra spectrum of J1306 are consistent with the values found for lower redshift radio-quiet quasars (Brandt et al. 2002). Specifically, our result for $\alpha_{ox}$ is consistent with no strong evolution in $\alpha_{ox}$ for optically selected radio-quiet quasars out to $z \approx 6$. A preprint by Farrah et al. (2004) gives an XMM spectrum of SDSS J1030+0524, a quasar at $z=6.30$. They reach very similar conclusions as to the spectrum and luminosity, and implications for lack of evolution. While XMM affords higher statistics, the $45''$ extraction radius gives less certainty on the precise origin of the flux. Thus the two observations are somewhat complementary.

X-ray studies of high-redshift quasars reveal the conditions in the immediate vicinity of their supermassive black holes. Our spectrum of J1306 hints at the presence of an Fe-K emission line. Our poorly determined EW of 114 eV is consistent with the scatter in compilations by Nandra et al. (1997) and Page et al. (2004) which would extrapolate to predict a $\approx 70$ eV EW for a radio-quiet quasar of the $2 \times 10^{45}$ ergs s$^{-1}$ luminosity. Recent near-infrared spectroscopy of three other high redshift SDSS quasars ($z \geq 5.7$) with the Hubble Space Telescope (Freudling et al. 2003) clearly detected Fe II emission lines at 2200-2600 Å (rest frame) and the Keck-II observations of Barth et al. (2003) have detected Si IV, C IV, Mg II, and the 2900-3000 Å Fe line complex. Both results indicate that the strength of the line complex, as well as the Fe II/Mg II ratio, is comparable to that of lower redshift quasars. The results of near-infrared studies such as these as well as the results of X-ray studies such as the one presented here and elsewhere (Brandt et al. 2002; Vignali et al. 2003) are beginning to indicate that there apparently is no strong evolution in the broadband AGN emission mechanism with redshift out to $z \approx 6$. This conclusion, if confirmed with a larger sample, implies that formation of the central black hole engines can be completed in less than 1 Gyr after the big bang, with the inference that a massive galaxy in which
they are imbedded has also formed. Therefore, in order to address the question of which, if any, of the observed quasar properties evolve with time, we must probe deeper still to identify quasars at even higher redshifts. This might best be done with the Chandra deep surveys, e.g., by identifying the objects with extreme X-ray-to-optical flux ratios found by Koekemoer et al. (2004).
